

Figure 1. Scheme of sections. The solid arrow represents relation.

1. RELATIVE ENTROPY

1.1. A Brief Review of Probability

Those that are not deterministic are denoted by capital letters. But, a capital letter may also denote something that is determined. For example, a random variable has to be denoted by capital letter, like X , while we can also use F to denote something determined, such as a functional.

The set of all possible values of a random variable is called the **alphabet**.¹ And for each value in the alphabet, we assign a *positive* value called **density** if the alphabet is of continuum (continuous random variable), or **mass** otherwise (discrete random variable).² We use **distribution** for not only the mass or density on the alphabet, but also a sampler that can sample an ensemble of values of the random variable that converges to the mass or density when the number of sample tends to infinity. For example, we say X is a random variable with alphabet \mathcal{X} and distribution P .

The density of a value x is usually denoted by $p(x)$, which, as a function, is called **density function**. Notice that $p(x)$ is deterministic, thus not capital. The same for mass, where $p(x)$ is called **mass function**. Thus, we can say the expectation of a function f on distribution P , denoted by $\mathbb{E}_P[f]$ or $\mathbb{E}_{x \sim P}[f(x)]$. If the alphabet \mathcal{X} is of continuum, then it is $\int_{\mathcal{X}} dx p(x) f(x)$, otherwise $\sum_{x \in \mathcal{X}} p(x) f(x)$.

If there exists random variables Y and Z , with alphabets \mathcal{Y} and \mathcal{Z} respectively, such that $X = Y \oplus Z$ (for example, let X two-dimensional, Y and Z are the components), then we have **marginal distributions**, denoted by P_Y and P_Z , where $p_Y(y) := \int_{\mathcal{Z}} dz p(y, z)$ and $p_Z(z) := \int_{\mathcal{Y}} dy p(y, z)$ if X is of continuum, and the same for mass function. We **marginalize** Z so as to get P_Y .

1.2. Shannon Entropy Is Plausible for Discrete Variable

The Shannon entropy is well-defined for discrete random variable. Let X a discrete random variables with alphabet $\{1, \dots, n\}$ with p_i the mass of $X = i$. The Shannon entropy is thus a function of (p_1, \dots, p_n) defined by

$$H(P) := -k \sum_{i=1}^n p_i \ln p_i,$$

1. Some textures call it **sample space**. But “space” usually hints for extra structures such as vector space or topological space. So, we use “alphabet” instead (following David Mackay, see his book *Information Theory, Inference, and Learning Algorithms*, section 2.1. Link to free PDF: <https://www.inference.org.uk/itprnn/book.pdf>).

2. In many textures, the density or mass function is non-negative (rather than being positive). Being positive is beneficial because, for example, we will discuss the logarithm of density or mass function, for which being zero is invalid. For any value on which density or mass function vanishes, we throw it out of \mathcal{X} , which in turn guarantees the positivity.

where k is a positive constant. Interestingly, this expression is unique given some plausible conditions, which can be qualitatively expressed as

1. H is a continuous function of (p_1, \dots, p_n) ;
2. larger alphabet has higher uncertainty (information or entropy); and
3. if we have known some information, and based on this knowledge we know further, the total information shall be the sum of all that we know.

Here, we use **uncertainty**, **surprise**, **information**, and **entropy** as interchangeable.

The third condition is also called the additivity of information. For two independent variables X and Y with distributions P and Q respectively, the third condition indicates that the total information of $H(PQ)$ is $H(P) + H(Q)$. But, the third condition indicates more than this. It also defines a “conditional entropy” for dealing with the situation where X and Y are dependent. Jaynes gives a detailed declaration to these conditions.³ This conditional entropy is, argued by others, quite strong and not sufficiently natural. The problem is that this stronger condition is essential for Shannon entropy to arise. Otherwise, there will be other entropy definitions that satisfy all the conditions, where the third involves only independent random variables, such as Rényi entropy.⁴

As we will see, when extending the alphabet to continuum, this problem naturally ceases.

1.3. Shannon Entropy Fails for Continuous Random Variable

The Shannon entropy, however, cannot be directly generalized to continuous random variable. Usually, the entropy for continuous random variable X with alphabet \mathcal{X} and distribution P is given as a functional of the density function $p(x)$,

$$H(P) := -k \int_{\mathcal{X}} dx p(x) \ln p(x)$$

which, however, is not well-defined. The first issue is that the p has dimension, indicated by $\int_{\mathcal{X}} dx p(x) = 1$. This means we put a dimensional quantity into logarithm which is not valid. The second issue is that the H is not invariant under coordinate transformation $X \rightarrow Y := \varphi(X)$ where φ is a diffeomorphism. But as a “physical” quantity, H should be invariant under “non-physical” transformations.

To eliminate the two issues, we shall extend the axiomatic description of entropy. The key to this extension is introducing another distribution, Q , which has the same alphabet as P ; and instead considering *the uncertainty (surprise) caused by P when prior knowledge has been given by Q* . As we will see, this will solve the two issues altogether.

Explicitly, we extend the conditions as

1. H is a smooth and local functional of p and q ;
2. $H(P, Q) > 0$ if $P \neq Q$ and $H[P, P] = 0$; and
3. If $X = Y \oplus Z$, and if Y and Z independent, then $H(P, Q) = H(P_Y, Q_Y) + H(P_Z, Q_Z)$, where P_Y, \dots, Q_Z are marginal distributions.

3. See the appendix A of *Information Theory and Statistical Mechanics* by E. T. Jaynes, 1957. A free PDF version can be found on Internet: <https://bayes.wustl.edu/etj/articles/theory.1.pdf>.

4. *On measures of information and entropy* by Alfréd Rényi, 1961. A free PDF version can be found on Internet: http://digitalassets.lib.berkeley.edu/math/ucb/text/math_s4_v1_article-27.pdf.

The first condition employs the locality of H , which is thought as natural since H has to be a functional. The second condition indicates that H vanishes only when there is no surprise caused by P (thus $P=Q$). It is a little like the second condition for Shannon entropy. The third condition, like the third in Shannon entropy, claims the additivity of surprise: if X has two independent parts, the total surprise shall be the sum of each.

1.4. Relative Entropy is Unique Solution to the Conditions

We are to derive the explicit expression of H based on the three conditions. The result is found to be unique.

Based on the first condition, there is a function $h: (0, +\infty) \times (0, +\infty) \rightarrow [0, +\infty)$ such that H can be expressed as

$$H(P, Q) = \int_{\mathcal{X}} dx p(x) h(p(x), q(x)).$$

We are to determine the explicit form of h . Thus, from second condition,

$$H(P, P) = \int_{\mathcal{X}} dx p(x) h(p(x), p(x)) = 0$$

holds for all distribution P . Since p is positive and h is non-negative, then we have $h(p(x), p(x)) = 0$ for all $x \in \mathcal{X}$. The distribution P is arbitrary, thus we find $h(x, x) = 0$ for any $x \in (0, +\infty)$.

Now come to the third condition. Since Y and Z are independent, $H(P, Q)$ can be written as $\int_{\mathcal{X}} dy dz p_Y(y) p_Z(z) h(p_Y(y) p_Z(z), q_Y(y) q_Z(z))$. Thus, the third condition implies

$$\int_{\mathcal{X}} dy dz p_Y(y) p_Z(z) [h(p_Y(y) p_Z(z), q_Y(y) q_Z(z)) - h(p_Y(y), q_Y(y)) - h(p_Z(z), q_Z(z))] = 0.$$

Following the previous argument, we find $h(ax, by) = h(a, b) + h(x, y)$ for any $a, b, x, y \in (0, +\infty)$. Taking derivative on a and b results in $\partial_1 h(ax, by) x = \partial_1 h(a, b)$ and $\partial_2 h(ax, by) y = \partial_2 h(a, b)$. Since $\partial_1 h(a, a) + \partial_2 h(a, a) = (d/da) h(a, a) = 0$, we get $\partial_1 h(ax, ay) x + \partial_2 h(ax, ay) y = 0$. Letting $a = 1$, it becomes a first order partial differential equation $\partial_1 h(x, y) x + \partial_2 h(x, y) y = 0$, which has a unique solution that $h(xe^t, ye^t)$ is constant for all t . Choosing $t = -\ln y$, we find $h(x, y) = h(x/y, 1)$. Now h reduces from two variables to one. So, plugging this result back to $h(ax, by) = h(a, b) + h(x, y)$, we have $h(xy, 1) = h(x, 1) + h(y, 1)$. It looks like a logarithm. We are to show that it is indeed so. By taking derivative on x and then letting $y = 1$, we get an first order ordinary differential equation $\partial_1 h(x, 1) = \partial_1 h(1, 1)/x$, which has a unique solution that $h(x, 1) = \partial_1 h(1, 1) \ln(x) + C$, where C is a constant. Combined with $h(x, y) = h(x/y, 1)$, we finally arrive at $h(x, y) = \partial_1 h(1, 1) \ln(x/y) + C$. To determine the $\partial_1 h(1, 1)$ and C , we use the second condition $\partial_1 h(1, 1) \int dx p(x) \ln(p(x)/q(x)) + C > 0$ when $p \neq q$ and $\partial_1 h(1, 1) \int dx p(x) \ln(p(x)/p(x)) + C = 0$. By **Jensen's inequality**, the integral $\int dx p(x) \ln(p(x)/q(x))$ is non-negative, thus $\partial_1 h(1, 1) > 0$. The second equation results in $C = 0$. Up to now, all things about h have been settled. We conclude that there is a unique expression that satisfies all the three conditions, which is

$$H(P, Q) = k \int_{\mathcal{X}} dx p(x) \ln \frac{p(x)}{q(x)},$$

where $k > 0$. This was first derived by **Solomon Kullback** and **Richard Leibler** in 1951, so it is called **Kullback–Leibler divergence (KL-divergence for short)**, denoted by $D_{\text{KL}}(P||Q)$. Since it characterizes the relative surprise, it is also called **relative entropy** (entropy for surprise).

The locality is essential for relative entropy to arise. For example, Renyi divergence, defined by

$$H_{\alpha}(P, Q) = \frac{1}{\alpha - 1} \ln \left(\int_{\mathcal{X}} dx \frac{p^{\alpha}(x)}{q^{\alpha-1}(x)} \right),$$

also satisfies the three conditions when locality is absent.

2. MASTER EQUATION, DETAILED BALANCE, AND RELATIVE ENTROPY

2.1. Conventions in This Section

Let X a multi-dimensional random variables, being, discrete, continuous, or partially discrete and partially continuous, with alphabet \mathcal{X} and distribution P . Even though the discussion in this section applies to both discrete and continuous random variables, we use the notation of the continuous. The reason is that converting from discrete to continuous may cause problems (section 1.3), while the inverse will be safe and direct as long as any smooth structure of X is not employed throughout the discussion.

2.2. Master Equation Describes the Evolution of Markov Process

Without losing generality, consider a pile of sand on a desk. The desk has been fenced in so that the sands will not flow out of the desk. Imagine that these sands are magic, having free will to move on the desk. The distribution of sands changes with time. In the language of probability, the density of sands at position x of the desk is described by a time-dependent density function $p(x, t)$, where the total mass of the sands on the desk is normalized to 1, and the position on the desk characterizes the alphabet \mathcal{X} .

Let $q_{t \rightarrow t'}(y|x)$ denote the *portion* of density at position x that transits to position y , from t to t' . Then, the transited density will be $q_{t \rightarrow t'}(y|x)p(x, t)$. There may be some portion of density at position x that does not transit during $t \rightarrow t'$ (the lazy sands). In this case we imagine the sands transit from position x to x (stay on x), which is $q_{t \rightarrow t'}(x|x)$. Now, every sand at position x has transited during $t \rightarrow t'$, and the total portion shall be 100%, which means

$$\int_{\mathcal{X}} dy q_{t \rightarrow t'}(y|x) = 1. \quad (1)$$

As portion, $q_{t \rightarrow t'}$ cannot be negative, thus $q_{t \rightarrow t'}(x|y) \geq 0$ for each x and y in \mathcal{X} . We call $q_{t \rightarrow t'}$ the **transition density**. Not like the density function of distribution, transition density can be zero in a subset of \mathcal{X} .

The transition makes a difference on density at position x . The difference is caused by the density transited from x , which is $\int_{\mathcal{X}} dy q_{t \rightarrow t'}(y|x)p(x, t)$, and that transited to x , which is $\int_{\mathcal{X}} dy q_{t \rightarrow t'}(x|y)p(y, t)$. Thus, we have

$$p(x, t') - p(x, t) = \int_{\mathcal{X}} dy [q_{t \rightarrow t'}(x|y)p(y, t) - q_{t \rightarrow t'}(y|x)p(x, t)].$$

By inserting equation (1), we find

$$p(x, t') = \int_{\mathcal{X}} dy q_{t \rightarrow t'}(x|y)p(y, t), \quad (2)$$

which is called the **discrete time master equation**. When $t' = t$, we have $p(x, t) = \int_{\mathcal{X}} dy q_{t \rightarrow t}(x|y)p(y, t)$, indicating that

$$q_{t \rightarrow t}(x|y) = \delta(x - y).$$

In addition, if the change of the distribution of sands is smooth, that is, there is not a sand lump that jumping from one place to another in an arbitrarily short period of time, then $q_{t \rightarrow t'}$ is smooth on t' . Taking derivative on t' and then setting t' to t , we have

$$\frac{\partial p}{\partial t}(x, t) = \int_{\mathcal{X}} dy r_t(x, y)p(y, t),$$

where $r_t(x, y) := \lim_{t' \rightarrow t} (\partial q_{t \rightarrow t'} / \partial t')(x|y)$, called **transition rate**. It is called the **continuous time master equation**, or simply **master equation**. The word “master” indicates that the transition rate has completely determined (mastered) the evolutionary behavior of distribution.

Even though all these concepts are born of the pile of sand, they are applicable to any stochastic process where the distribution $P(t)$ is time-dependent (but the alphabet \mathcal{X} is time-invariant), no matter whether the random variable is discrete or continuous.

A stochastic process is **Markovian** if the transition density $q_{t \rightarrow t'}$ depends only on the time interval $\Delta t := t' - t$, thus $q_{\Delta t}$. In this case, transition rate r is time-independent, so the master equation becomes

$$\frac{\partial p}{\partial t}(x, t) = \int_{\mathcal{X}} dy r(x, y) p(y, t). \quad (3)$$

Since we only deal with Markovian stochastic process throughout this note, when referring to master equation, we mean equation 3. And to discrete time master equation, equation 4:

$$p(x, t + \Delta t) = \int_{\mathcal{X}} dy q_{\Delta t}(x, y) p(y, t). \quad (4)$$

Before finishing this section, we discuss the demanded conditions for transition rate. The normalization of transition density 1 implies that $\int_{\mathcal{X}} dx r(x, y) = 0$. This can be seen by Taylor expanding $q_{\Delta t}$ by Δt , as $q_{\Delta t}(x|y) = \delta(x - y) + r(x, y) \Delta t + o(\Delta t)$, where we have inserted $q_0(x|y) = \delta(x - y)$ and the definition of r . Also from this Taylor expansion, we see that the non-negativity of $q_{\Delta t}$ implies $r(x, y) \geq 0$ when $x \neq y$. Since p is a density function of distribution, and density function is defined to be positive (see section 1.1), the equation 2 must conserve this positivity. We are to show that this is guaranteed by the master equation itself, without any extra condition demanded for the transition rate. It is convenient to use discrete notations, thus replace $x \rightarrow i$, $y \rightarrow j$, and $\int \rightarrow \sum$. The master equation turns to be $(dp_i/dt)(t) = \sum_j r_{ij} p_j(t)$. Notice that it becomes an ordinary differential equation. Recall that $r_{ij} \geq 0$ when $i \neq j$, and thus $r_{ii} \leq 0$ (since $\sum_j r_{ji} = 0$). We separate the right hand side to $r_{ii} p_i(t) + \sum_{j: j \neq i} r_{ij} p_j(t)$, and the worst situation is that $r_{ij} = 0$ for each $j \neq i$ and $r_{ii} < 0$. In this case, the master equation reduces to $(dp_i/dt)(t) = r_{ii} p_i(t)$, which has the solution $p_i(t) = p_i(0) \exp(r_{ii} t)$. It implies that $p_i(t) > 0$ as long as $p_i(0) > 0$, indicating that master equation conserves the positivity of density function. As a summary, we demand transition rate r to be $r(x, y) \geq 0$ when $x \neq y$ and $\int_{\mathcal{X}} dx r(x, y) = 0$.

2.3. Transition Rate Determines Transition Density

We wonder, given a transition rate, can we obtain the corresponding transition density? Generally, we cannot get the global (finite) from the local (infinitesimal). For example, we cannot determine a function only by its first derivative at the origin. But, master equation has a group-like structure, by which the local accumulates to be global. We are to show how this happens.

We can use the master equation 3 to calculate $\partial^n p / \partial t^n$ for any n . Indeed, for $n = 2$,

$$\begin{aligned} \frac{\partial^2 p}{\partial t^2}(z, t) &= \frac{\partial}{\partial t} \int_{\mathcal{X}} dy r(z, y) p(y, t) \\ \{\text{exchange limits}\} &= \int_{\mathcal{X}} dy r(z, y) \frac{\partial p}{\partial t}(y, t) \\ \{\text{insert equation 3}\} &= \int_{\mathcal{X}} dy r(z, y) \int_{\mathcal{X}} dx r(y, x) p(x, t) \\ \{\text{rearrange}\} &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(z, y) r(y, x) p(x, t). \end{aligned}$$

Following the same steps, it can be generalized to higher order derivatives, as

$$\frac{\partial^{n+1} p}{\partial t^{n+1}}(z, t) = \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy_1 \cdots \int_{\mathcal{X}} dy_n r(z, y_n) r(y_n, y_{n-1}) \cdots r(y_1, x) p(x, t).$$

Notice the pattern: a sequence of r and a rightmost $p(x, t)$. The reason for this pattern to arise is that $q_{\Delta t}$, thus r , is independent of t : a Markovian property.

Also, Taylor expand the both sides of equation 4 by Δt gives, at $(\Delta t)^{n+1}$ order,

$$\frac{\partial^{n+1} p}{\partial t^{n+1}}(z, t) = \int_{\mathcal{X}} dx \lim_{\Delta t \rightarrow 0} \frac{\partial^{n+1} q_{\Delta t}}{\partial (\Delta t)^{n+1}}(z|x) p(x, t).$$

So, we arrive at

$$\int_{\mathcal{X}} dx \left[\lim_{\Delta t \rightarrow 0} \frac{\partial^{n+1} q_{\Delta t}}{\partial (\Delta t)^{n+1}}(z|x) - \int_{\mathcal{X}} dy_1 \cdots \int_{\mathcal{X}} dy_n r(z, y_n) r(y_n, y_{n-1}) \cdots r(y_1, x) \right] p(x, t) = 0,$$

which holds for all $p(x, t)$, thus

$$\lim_{\Delta t \rightarrow 0} \frac{\partial^{n+1} q_{\Delta t}}{\partial (\Delta t)^{n+1}}(z|x) = \int_{\mathcal{X}} dy_1 \cdots \int_{\mathcal{X}} dy_n r(z, y_n) r(y_n, y_{n-1}) \cdots r(y_1, x),$$

or say⁵

$$\begin{aligned} q_{\Delta t}(z|x) &= \delta(z-x) \\ &+ (\Delta t) r(z, x) \\ &+ \frac{(\Delta t)^2}{2!} \int_{\mathcal{X}} dy r(z, y) r(y, x) \\ &+ \cdots \\ &+ \frac{(\Delta t)^{n+1}}{(n+1)!} \int_{\mathcal{X}} dy_1 \cdots \int_{\mathcal{X}} dy_n r(z, y_n) r(y_n, y_{n-1}) \cdots r(y_1, x) \\ &+ \cdots. \end{aligned} \tag{5}$$

Well, this is a complicated formula, but its implication is straight forward and very impressive: *the transition density is equivalent to transition rate, even though transition rate is derived from infinitesimal time-interval transition density.*

This may be a little weird at the first sight. For example, consider another transition density $q'_{\Delta t}(y|x) = q_{\Delta t}(y|x) + f(y, x) \Delta t^2$, where f is any function ensuring that $q'_{\Delta t}$ is non-negative and normalized (thus $\int_{\mathcal{X}} dy f(y, x) = 0$). Following the previous derivation, we find that the discrete time master equation

$$p(z, t + \Delta t) = \int_{\mathcal{X}} dx q'_{\Delta t}(z|x) p(x, t)$$

also leads to equation 3, the same r as that of $q_{\Delta t}$. So, we should have $q'_{\Delta t} = q_{\Delta t}$, which means f is not free, but should vanish.

5. Another derivation uses exponential mapping. By regarding p a time-dependent element in functional space, and r as a linear operator, it becomes (we add a hat for indicating operator, using dot \cdot for its operation)

$$\frac{dp}{dt}(t) = \hat{r} \cdot p(t).$$

This operator differential equation has a famous solution, called exponential mapping, $p(t) = \exp(\hat{r} t) p(0)$, where the exponential operator is defined by Taylor expansion $\exp(\hat{L}) := \hat{1} + \hat{L} + (1/2!) \hat{L}^2 + \cdots$ for any linear operator \hat{L} . Indeed, by taking derivative on t on both sides, we find $(dp/dt)(t) = \hat{r} \cdot \exp(\hat{r} t) p(0) = \hat{r} \cdot p(t)$. Recall the discrete time master equation, $p(\Delta t) = \hat{q}_{\Delta t} \cdot p(0)$, where the transition density $\hat{q}_{\Delta t}$ is regarded as a linear operator too (so we put a hat on it). We find $\exp(\hat{r} \Delta t) \cdot p(0) = \hat{q}_{\Delta t} \cdot p(0)$, which holds for arbitrary $p(0)$, implying $\hat{q}_{\Delta t} = \exp(\hat{r} \Delta t) = 1 + \hat{r} \Delta t + (1/2!) (\hat{r} \cdot \hat{r}) (\Delta t)^2 + \cdots$. Going back to functional representation, we have the correspondences $\hat{q}_{\Delta t} \rightarrow q_{\Delta t}(z|x)$, $\hat{r} \rightarrow r(z, x)$, $\hat{r} \cdot \hat{r} \rightarrow \int dy r(z, y) r(y, x)$, $\hat{r} \cdot \hat{r} \cdot \hat{r} \rightarrow \int dy_1 dy_2 r(z, y_2) r(y_2, y_1) r(y_1, x)$, and so on, thus recover the relation between $q_{\Delta t}$ and r .

The answer to this question is that, a transition density is not free to choose, but sharing the same degree of freedom as that of its transition rate. *The fundamental quantity that describes the evolution of a continuous time Markov process is transition rate.* For example, consider $p(z, t + \Delta t + \Delta t')$ for any Δt and $\Delta t'$. Directly, we have

$$p(z, t + \Delta t + \Delta t') = \int_{\mathcal{X}} dx q_{\Delta t + \Delta t'}(z|x) p(x, t),$$

but on the other hand, by applying discrete time master equation twice, we find

$$\begin{aligned} p(z, t + \Delta t + \Delta t') &= \int_{\mathcal{X}} dy q_{\Delta t}(z|y) p(y, t + \Delta t') \\ &= \int_{\mathcal{X}} dy q_{\Delta t'}(z|y) \int_{\mathcal{X}} dx q_{\Delta t}(y|x) p(x, t). \end{aligned}$$

Thus,

$$\int_{\mathcal{X}} dx \left[q_{\Delta t + \Delta t'}(z|x) - \int_{\mathcal{X}} dy q_{\Delta t'}(z|y) q_{\Delta t}(y|x) \right] p(x, t) = 0.$$

Since $p(x, t)$ can be arbitrary, we arrive at

$$q_{\Delta t + \Delta t'}(z|x) = \int_{\mathcal{X}} dy q_{\Delta t'}(z|y) q_{\Delta t}(y|x).$$

This provides an addition restriction to the transition density. Indeed, not every transition density, as a function of time interval Δt , can satisfy this relation.

2.4. Detailed Balance Provides Stationary Distribution

Let Π a stationary solution of master equation 3. Then, its density function π satisfies $\int_{\mathcal{X}} dy r(x, y) \pi(y) = 0$. Since we have demanded that $\int_{\mathcal{X}} dy r(y, x) = 0$, the stationary master equation can be re-written as

$$\int_{\mathcal{X}} dy [r(x, y) \pi(y) - r(y, x) \pi(x)] = 0.$$

But, this condition is too weak to be used. A more useful condition, which is stronger than this, is that the integrand vanishes everywhere:

$$r(x, y) \pi(y) = r(y, x) \pi(x), \quad (6)$$

which is called the **detailed balance condition**.

Interestingly, for a transition rate r that satisfies detailed balance condition 6, the transition density $q_{\Delta t}$ generated by r using equation 5 satisfies a similar relation

$$q_{\Delta t}(x|y) \pi(y) = q_{\Delta t}(y|x) \pi(x). \quad (7)$$

To see this, consider the third line in equation (5), where the main factor is

$$\begin{aligned} q_{\Delta t}(z|x) \pi(x) &\supset \int dy r(z, y) r(y, x) \pi(x) \\ \{r(y, x) \pi(x) = \pi(y) r(x, y)\} &= \int dy r(z, y) \pi(y) r(x, y) \\ \{r(z, y) \pi(y) = \pi(z) r(x, y)\} &= \int dy \pi(z) r(x, y) r(y, z) \\ &= \pi(z) \int dy r(x, y) r(y, z) \\ &\subset q_{\Delta t}(x|z) \pi(z) \end{aligned}$$

Following the same steps, we can show that all terms in equation 5 share the same relation, indicating $q_{\Delta t}(z|x) \pi(x) = q_{\Delta t}(x|z) \pi(z)$.

2.5. Detailed Balance Condition and Connectivity Monotonically Reduce Relative Entropy

Given the time t , if the time-dependent distribution $P(t)$ and the stationary distribution Π share the same alphabet \mathcal{X} , which means $p(x, t) > 0$ and $\pi(x) > 0$ for each $x \in \mathcal{X}$, we have defined the relative entropy between them, as

$$H(P(t), \Pi) = \int_{\mathcal{X}} dx p(x, t) \ln \frac{p(x, t)}{\pi(x)}. \quad (8)$$

It describes the uncertainty (surprise) caused by $P(t)$ when prior knowledge is given by Π . It is a plausible generalization of Shannon entropy to continuous random variables.

We can calculate the time-derivative of relative entropy by master equation 3. Generally, the time-derivative of relative entropy has no interesting property. But, if the π is more than stationary but satisfying a stronger condition: detailed balance, then $dH(P(t), \Pi)/dt$ will have a regular form⁶

$$\frac{d}{dt} H(P(t), \Pi) = -\frac{1}{2} \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(x) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \left(\ln \frac{p(x, t)}{\pi(x)} - \ln \frac{p(y, t)}{\pi(y)} \right). \quad (9)$$

6. The proof is given as follow. Directly, we have

$$\begin{aligned} \frac{d}{dt} H(P(t), \Pi) &= \frac{d}{dt} \int_{\mathcal{X}} dx [p(x, t) \ln p(x, t) - p(x, t) \ln \pi(x)] \\ &= \int_{\mathcal{X}} dx \left(\frac{\partial p}{\partial t}(x, t) \ln p(x, t) + \frac{\partial p}{\partial t}(x, t) - \frac{\partial p}{\partial t}(x, t) \ln \pi(x) \right). \end{aligned}$$

Since $\int_{\mathcal{X}} dx (\partial p / \partial t)(x, t) = (\partial / \partial t) \int_{\mathcal{X}} dx p(x, t) = 0$, the second term vanishes. Then, we get

$$\frac{d}{dt} H(P(t), \Pi) = \int_{\mathcal{X}} dx \frac{\partial p}{\partial t}(x, t) \ln \frac{p(x, t)}{\pi(x)}.$$

Now, we replace $\partial p / \partial t$ by master equation 3, as

$$\frac{d}{dt} H(P(t), \Pi) = \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy [r(x, y) p(y, t) - r(y, x) p(x, t)] \ln \frac{p(x, t)}{\pi(x)},$$

Then, insert detailed balance condition $r(y, x) = r(x, y) \pi(y) / \pi(x)$, as

$$\begin{aligned} \frac{d}{dt} H(P(t), \Pi) &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy \left(r(x, y) p(y, t) - r(x, y) \pi(y) \frac{p(x, t)}{\pi(x)} \right) \ln \frac{p(x, t)}{\pi(x)} \\ &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(y) \left(\frac{p(y, t)}{\pi(y)} - \frac{p(x, t)}{\pi(x)} \right) \ln \frac{p(x, t)}{\pi(x)}. \end{aligned}$$

Since x and y are dummy, we interchange them in the integrand, and then insert detailed balance condition again, as

$$\begin{aligned} \frac{d}{dt} H(P(t), \Pi) &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(y, x) \pi(x) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \ln \frac{p(y, t)}{\pi(y)} \\ \{\text{detailed balance}\} &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(y) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \ln \frac{p(y, t)}{\pi(y)}. \end{aligned}$$

By adding the two previous results together, we find

$$\begin{aligned} &2 \frac{d}{dt} H(P(t), \Pi) \\ [\text{1st result}] &= \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(y) \left(\frac{p(y, t)}{\pi(y)} - \frac{p(x, t)}{\pi(x)} \right) \ln \frac{p(x, t)}{\pi(x)} \\ [\text{2nd result}] &+ \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(y) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \ln \frac{p(y, t)}{\pi(y)} \\ &= - \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \pi(y) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \left(\ln \frac{p(x, t)}{\pi(x)} - \ln \frac{p(y, t)}{\pi(y)} \right), \end{aligned}$$

from which we directly get the result. Notice that this proof is very tricky: it uses detailed balance condition twice, between which the expression is symmetrized. It is an ingenious mathematical engineering.

We are to check the sign of the integrand. The $r(x, y)$ is negative only when $x = y$, on which the integrand vanishes. Thus, $r(x, y)$ can be treated as non-negative, so is the $r(x, y)\pi(y)$ (since $\pi(x) > 0$ for all $x \in \mathcal{X}$). Now, we check the sign of the last two terms. If $p(x, t)/\pi(x) > p(y, t)/\pi(y)$, then $\ln[p(x, t)/\pi(x)] > \ln[p(y, t)/\pi(y)]$, thus the sign of the last two terms is positive. The same goes for $p(x, t)/\pi(x) < p(y, t)/\pi(y)$. Only when $p(x, t)/\pi(x) = p(y, t)/\pi(y)$ can it be zero. Altogether, the integrand is non-positive, thus $dH/dt \leq 0$.

The integrand vanishes when either $r(x, y) = 0$ or $p(x, t)/\pi(x) = p(y, t)/\pi(y)$. If $r(x, y) > 0$ for each $x \neq y$, then $(d/dt)H(P(t), \Pi) = 0$ only when $p(x, t)/\pi(x) = p(y, t)/\pi(y)$ for all $x, y \in \mathcal{X}$, which implies that $p(\cdot, t) = \pi$ (since $\int_{\mathcal{X}} dx p(x, t) = \int_{\mathcal{X}} dx \pi(x) = 1$), or $P(t) = \Pi$.

Contrarily, if $r(x, y) = 0$ on some subset $U \subset \mathcal{X} \times \mathcal{X}$, it seems that $(d/dt)H(P(t), \Pi) = 0$ cannot imply $p(x, t)/\pi(x) = p(y, t)/\pi(y)$ on U . But, if there is a $z \in \mathcal{X}$ such that both (x, z) and (y, z) are not in U , then $(d/dt)H(P(t), \Pi) = 0$ implies $p(x, t)/\pi(x) = p(z, t)/\pi(z)$ and $p(y, t)/\pi(y) = p(z, t)/\pi(z)$, thus implies $p(x, t)/\pi(x) = p(y, t)/\pi(y)$. It hints for connectivity. Precisely, for each $x, z \in \mathcal{X}$, if there is a series (y_1, \dots, y_n) from x ($y_1 := x$) to z ($y_n := z$) with both $r(y_{i+1}, y_i)$ and $r(y_i, y_{i+1})$ are positive for each i , then we say x and z are **connected**, and the series is called a **path**. It means *there are densities transiting along the forward and backward directions of the path*. In this situation, $(d/dt)H(P(t), \Pi) = 0$ implies $p(x, t)/\pi(x) = p(z, t)/\pi(z)$.⁷ So, by repeating the previous discussion on the case “ $r(x, y) > 0$ for each $x \neq y$ ”, we find $P(t) = \Pi$ at $(d/dt)H(P(t), \Pi) = 0$ if every two elements in \mathcal{X} are connected.

Let us examine the connectivity further. We additionally *define* that every element in \mathcal{X} is connected to itself, then connectivity forms an equivalence relation. So, it separates \mathcal{X} into subsets (equivalence classes) $\mathcal{X}_1, \dots, \mathcal{X}_n$ with $\mathcal{X}_i \cap \mathcal{X}_j = \emptyset$ for each $i \neq j$ and $\mathcal{X} = \cup_{i=1}^n \mathcal{X}_i$. In each subset \mathcal{X}_i , every two elements are connected. In this way, the whole random system are separated into many independent subsystems. The distributions $P_i(t)$ and Π_i defined in the subsystem i have the alphabet \mathcal{X}_i and densities functions $p_i(x, t) := p(x, t) / \int_{\mathcal{X}_i} dx p(x, t)$ and $\pi_i(x) := \pi(x) / \int_{\mathcal{X}_i} dx \pi(x)$ respectively (the denominators are used for normalization). Applying the previous discussion to this subsystem, we find $P_i(t) = \Pi_i$ at $(d/dt)H(P_i(t), \Pi_i) = 0$.

So, for the whole random system or each of its subsystems, the following theorem holds.

THEOREM 1. *Let Π a distribution with alphabet \mathcal{X} . If there is a transition rate r such that 1) every two elements in \mathcal{X} are connected and that 2) the detailed balance condition 6 holds for Π and r , then for any time-dependent distribution $P(t)$ with the same alphabet (at one time) evolved by the master equation 3, $P(t)$ will monotonically and constantly relax to Π .*

Many textures use Fokker-Planck equation to prove the monotonic reduction of relative entropy. With an integral by part, they arrive at a negative definite expression, which means the monotonic reduction. This proof needs smooth structure on X , which is essential for integral by part. In this section, we provides a more generic alternative to the proof, for which smooth structure on X is unnecessary. It employs detailed condition instead of Fokker-Planck equation, which is a specific case of detailed balance (section ?).

2.6. Numerical Simulation of Master Equation and Guarantee of Relaxation

How to solve master equation 3? When the alphabet \mathcal{X} is discrete and finite, where the desk becomes a finite two-dimensional array of lattices (recall section 2.2), we replace position by its index in the alphabet, like $x \rightarrow i$. Then, master equation becomes autonomous linear dynamical system: $(d/dt)p_i(t) = \sum_{j \in \mathcal{X}} r_{ij} p_j(t)$. It can be solved analytically, by investigating the eigen-system of matrix r .

⁷ We have, along the path, $p(y_1, t)/\pi(y_1) = p(y_2, t)/\pi(y_2) = \dots = p(y_n, t)/\pi(y_n)$, thus $p(x, t)/\pi(x) = p(z, t)/\pi(z)$ since $x = y_1$ and $z = y_n$.

When alphabet \mathcal{X} is neither discrete nor finite, we can approximate the solution by using some properties of r . To do so, we expand $p(x, t)$ by a set of bases of Hilbert space, $\{\alpha_1, \alpha_2, \dots\}$, as $p(x, t) = \sum_i \xi_i(t) \alpha_i(x)$, where ξ is the coefficient. The master equation turns to be

$$\sum_k \frac{d\xi_k}{dt}(t) \alpha_k(x) = \int_{\mathcal{X}} dy r(x, y) \sum_j \xi_j(t) \alpha_j(x).$$

By inner product with $\alpha_i(x)$ on both side, we find

$$\frac{d\xi_i}{dt}(t) \alpha_i(x) = \sum_j \left[\int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \alpha_i(x) \alpha_j(y) \right] \xi_j(t).$$

If the r is specific (such as slowly varying) and the bases are properly chosen such that $\int_{\mathcal{X}} dx \int_{\mathcal{X}} dy r(x, y) \alpha_i(x) \alpha_j(y)$ is negligible for any i and j greater than a number, the problem reduces to the case when \mathcal{X} is discrete and finite.

In the worst situation, we have to solve master equation by numerical simulation. We simulate each sand, but replace its free will by a transition probability determined by transition rate r . Explicitly, we initialize the sand randomly. Then iteratively update the position of each sand. In each iteration, a sand jumps from position x to position y with the probability $q_{\Delta t}(y|x) \approx \delta(y-x) + r(y, x) \Delta t$ where Δt is sufficiently small. *We have to ensure that computer has a sampler that makes random sampling for $q_{\Delta t}(y|x)$* (as an example, see section 2.7). If r together with some stationary distribution Π satisfies the detailed balance condition, then we *expect* that the simulation will iteratively decrease the difference between the distribution of the sands and the Π . We stop the iteration when they have been close enough.

Like the Euler method in solving dynamical system, however, a finite time step results in a residual error. This residual error must be analyzed and controlled, so that the distribution will evaluate toward Π , as we have expected. To examine this, we calculate the $H(P(t + \Delta t), \Pi) - H(P(t), \Pi)$ where Δt is small but still finite, and check when it is negative (such that $H(P(t))$ monotonically decreases to $P(t) \rightarrow \Pi$).

By definition, we have

$$\Delta H := H(P(t + \Delta t), \Pi) - H(P(t), \Pi) = \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t + \Delta t)}{\pi(x)} - \int_{\mathcal{X}} dx p(x, t) \ln \frac{p(x, t)}{\pi(x)}.$$

Inserting $\int_{\mathcal{X}} dx p(x, t + \Delta t) \ln(p(x, t) / \pi(x, t))$ gives

$$\begin{aligned} \Delta H &= \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t + \Delta t)}{\pi(x)} - \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t)}{\pi(x)} \\ &\quad + \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t)}{\pi(x)} - \int_{\mathcal{X}} dx p(x, t) \ln \frac{p(x, t)}{\pi(x)} \\ &= \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t + \Delta t)}{p(x, t)} \\ &\quad + \int_{\mathcal{X}} dx [p(x, t + \Delta t) - p(x, t)] \ln \frac{p(x, t)}{\pi(x)} \end{aligned}$$

The first line is recognized as $H(P(t + \Delta t), P(t))$, which is non-negative. Following the same steps in section 2.5 (but using discrete time master equation 4 instead, and detailed balance condition 7 for transition density), the second line reduces to

$$-\frac{1}{2} \int_{\mathcal{X}} dx \int_{\mathcal{X}} dy q_{\Delta t}(x|y) \pi(y) \left(\frac{p(x, t)}{\pi(x)} - \frac{p(y, t)}{\pi(y)} \right) \left(\ln \frac{p(x, t)}{\pi(x)} - \ln \frac{p(y, t)}{\pi(y)} \right),$$

which is non-positive (suppose that r connects every two elements in \mathcal{X}). So, the sign of ΔH is determined by that which line has greater absolute value. The first line depends only on the difference between $P(t)$ and $P(t + \Delta t)$, thus Δt , while the second line additionally depends on the difference between $P(t)$ and Π (the factor $q_{\Delta t}(x|y)$ also depends on Δt). When $\Delta t \rightarrow 0$, the first line vanishes, while the second does not until $P(t) \rightarrow \Pi$. This suggests us to investigate how fast each term converges as $\Delta t \rightarrow 0$.

To examine the speed of convergence, we calculate the leading order of Δt in each line. To make it clear, we denote the first line by ΔH_1 and the second line ΔH_2 . Taylor expanding ΔH_1 by Δt gives⁸

$$\Delta H_1 = \frac{\Delta t^2}{2} \int_{\mathcal{X}} dx p(x, t) \left(\frac{\partial}{\partial t} \ln p(x, t) \right)^2 + o(\Delta t^2),$$

where, by master equation 3, $(\partial / \partial t) \ln p(x, t) = \int_{\mathcal{X}} dx r(x, y) p(y, t) / p(x, t)$. The same for ΔH_1 , which results in

$$\Delta H_2 = \Delta t \frac{d}{dt} H(P(t), \Pi) + o(\Delta t),$$

where we have inserted equation 9. We find ΔH_1 converges with speed Δt^2 while ΔH_2 has speed Δt .

Thus, given $P(t) \neq \Pi$ (so that $\Delta H_2 \neq 0$, recall section 2.5), there must be a $\delta > 0$ such that for any $\Delta t < \delta$, we have $|\Delta H_1| < |\Delta H_2|$, in which case the $\Delta H = \Delta H_1 + \Delta H_2 < 0$ (recall that $\Delta H_1 \geq 0$ and $\Delta H_2 \leq 0$). The δ is bounded by

$$\delta \leq \left[-\frac{d}{dt} H(P(t), \Pi) \right] / \left[\frac{1}{2} \int_{\mathcal{X}} dx p(x, t) \left(\frac{\partial}{\partial t} \ln p(x, t) \right)^2 \right].$$

This bound is proportional to the difference between $P(t)$ and Π (represented by the first factor). When $P(t)$ has approached Π (that is, $P(t) \approx \Pi$ but not exactly equal), δ has to be extremely small. (This is a little like supervised machine learning where Δt acts as learning rate and $H(P(t), \Pi)$ as loss. In the early stage of training, the loss function has a greater slope and we can safely employ a relatively larger learning rate to speed up the decreasing of loss. But, we have to tune the learning rate to be smaller and smaller during the training, in which the slope of loss function is gradually decreasing. Otherwise, the loss will not decrease but keep fluctuating when it has been sufficiently small, since the learning rate now becomes relatively too big.)

8. The first line

$$\Delta H_1 := \int_{\mathcal{X}} dx p(x, t + \Delta t) \ln \frac{p(x, t + \Delta t)}{p(x, t)}$$

To Taylor expand the right hand side by Δt , we expand $p(x, t + \Delta t)$ to $o(\Delta t^2)$, as

$$p(x, t + \Delta t) = p(x, t) + \Delta t \frac{\partial p}{\partial t}(x, t) + \frac{\Delta t^2}{2!} \frac{\partial^2 p}{\partial t^2}(x, t) + o(\Delta t^2),$$

and the same for $\ln p(x, t + \Delta t)$, as

$$\ln p(x, t + \Delta t) = \ln p(x, t) + \Delta t \frac{\partial}{\partial t} \ln p(x, t) + \frac{\Delta t^2}{2!} \frac{\partial^2}{\partial t^2} \ln p(x, t) + o(\Delta t^2).$$

Plugging in $(d/dx) \ln f(x) = f'(x)/f(x)$ and then $(d^2/dx^2) \ln f(x) = f''(x)/f(x) - (f'(x)/f(x))^2$, we find

$$\ln p(x, t + \Delta t) - \ln p(x, t) = \Delta t \left[\frac{\partial p}{\partial t} p(x, t) p^{-1}(x, t) \right] + \frac{\Delta t^2}{2} \left[\frac{\partial^2 p}{\partial t^2}(x, t) p^{-1}(x, t) - \left(\frac{\partial p}{\partial t}(x, t) p^{-1}(x, t) \right)^2 \right] + o(\Delta t^2).$$

So, the Δt order term in ΔH_1 is

$$\int_{\mathcal{X}} dx p(x, t) \left[\frac{\partial p}{\partial t} p(x, t) p^{-1}(x, t) \right] = \int_{\mathcal{X}} dx \frac{\partial p}{\partial t} p(x, t) = \frac{\partial}{\partial t} \int_{\mathcal{X}} dx p(x, t) = 0,$$

where we used the normalization of p . The Δt^2 term in ΔH_1 is

$$\int_{\mathcal{X}} dx p(x, t) \frac{1}{2} \left[\frac{\partial^2 p}{\partial t^2}(x, t) p^{-1}(x, t) - \left(\frac{\partial p}{\partial t} p(x, t) p^{-1}(x, t) \right)^2 \right] + \frac{\partial p}{\partial t}(x, t) p^{-1}(x, t) \frac{\partial p}{\partial t}(x, t).$$

Using the normalization of p as before, it is reduced to

$$\frac{1}{2} \int_{\mathcal{X}} dx p(x, t) \left(\frac{\partial p}{\partial t} p(x, t) p^{-1}(x, t) \right)^2 = \frac{1}{2} \int_{\mathcal{X}} dx p(x, t) \left(\frac{\partial}{\partial t} \ln p(x, t) \right)^2.$$

Altogether, we arrive at

$$\Delta H_1 = \frac{\Delta t^2}{2} \int_{\mathcal{X}} dx p(x, t) \left(\frac{\partial}{\partial t} \ln p(x, t) \right)^2 + o(\Delta t^2).$$

2.7. Example: Metropolis-Hastings Algorithm

Metropolis-Hastings algorithm is a simple method that constructs transition rate for any given stationary distribution such that detailed balance condition holds. Explicitly, given a stationary distribution Π , and an auxiliary transition rate γ , ensuring that $\gamma(x, y) > 0$ for each x and y in alphabet \mathcal{X} such that $x \neq y$, the transition rate r is given by

$$r(x, y) = \min \left(1, \frac{\gamma(y, x) \pi(x)}{\gamma(x, y) \pi(y)} \right) \gamma(x, y). \quad (10)$$

This transition rate connects every two elements in \mathcal{X} (since $\gamma(y, x) > 0$ for each $x \neq y$). In addition, together with π , it satisfies the detailed balance condition 6. Directly,

$$\begin{aligned} & r(x, y) \pi(y) \\ \{\text{definition of } r\} &= \min \left(1, \frac{\gamma(y, x) \pi(x)}{\gamma(x, y) \pi(y)} \right) \gamma(x, y) \pi(y) \\ \{\text{property of min}\} &= \min (\gamma(x, y) \pi(y), \gamma(y, x) \pi(x)) \\ \{\text{property of min}\} &= \min \left(\frac{\gamma(x, y) \pi(y)}{\gamma(y, x) \pi(x)}, 1 \right) \gamma(y, x) \pi(x) \\ \{\text{definition of } r\} &= r(y, x) \pi(x). \end{aligned}$$

Thus detailed balance condition holds. So, theorem 1 states that, *evolved by the master equation 3, any initial distribution will finally relax to the stationary distribution Π .*

Metropolis-Hastings algorithm was first proposed by Nicholas Metropolis and others in 1953 in Los Alamos, and then improved by Canadian statistician Wilfred Hastings in 1970. This algorithm was first defined for transition density. Together with a positive auxiliary transition density g , the transition density is defined as

$$q(x|y) := \min \left(1, \frac{g(y|x) \pi(x)}{g(x|y) \pi(y)} \right) g(x|y), \quad (11)$$

where g is positive-definite on \mathcal{X} . Notice that, in equation 11 there is no extra time parameter like the $q_{\Delta t}(x|y)$ in section 2.2. It can be seen as a fixed time interval, which can only be used for discrete time master equation.

This definition has an intuitive and practical explanation. The two factors can be seen as two conditional probability. The factor $g(x|y)$ first proposes a transition from y to x . (In numerical simulation, we have to ensure that computer has a sampler for sampling an x from the conditional probability $g(x|y)$.) Then, this proposal will be accepted by Bernoulli probability with the ratio given by the first factor in the right hand side. If accepted, then transit to x , otherwise stay on y . Altogether, we get a conditional probability jumping from y to x , the $q(x|y)$.

It is straight forward to check that, if, in addition, g smoothly depends on a parameter Δt as $g_{\Delta t}$, so is q as $q_{\Delta t}$, and if we expand $g_{\Delta t}$ at $\Delta t \rightarrow 0$ as $g_{\Delta t}(x|y) = \delta(x - y) + \gamma(x, y) \Delta t + o(\Delta t)$, then we will find $q_{\Delta t}(x|y) = \delta(x - y) + r(x, y) \Delta t + o(\Delta t)$. Indeed, when $x = y$, we have $q_{\Delta t}(x|x) = g_{\Delta t}(x, x)$. And when $x \neq y$, $\delta(x - y) = 0$, we find

$$q_{\Delta t}(x|y) = \left[\min \left(1, \frac{\gamma(y, x) \pi(x) + o(1)}{\gamma(x, y) \pi(y) + o(1)} \right) (\gamma(x, y) + o(1)) \right] \Delta t.$$

Altogether, for each $x, y \in \mathcal{X}$, we find $q_{\Delta t}(x|y) = \delta(x - y) + r(x, y) \Delta t + o(\Delta t)$. In practice, we use the Metropolis-Hastings algorithm 11 to numerically simulate master equation 3. But, based on the discussion in section 2.6, the Δt in $g_{\Delta t}$ shall be properly bounded to be small (or equivalently speaking, g shall be “principal diagonal”) so as to ensure the relaxation $P(t) \rightarrow \Pi$.

2.8. * Existence of Stationary Density Function

Given a transition rate, we wonder if there exists a density function such that detailed balance condition 6 holds. Actually, equation 6 *defines* a density function. For example, if both $r(x, y)$ and $r(y, x)$ are not zero, we can construct $\pi(y)$ by given $\pi(x)$ as $\pi(y) = \pi(x) r(y, x) / r(x, y)$. Generally, if x and y are connected, then there is a path $P := (p_0, \dots, p_n)$ from x to y with $p_0 = x$ and $p_n = y$ (path and connectivity are defined in section 2.5), and define

$$\begin{aligned}\pi(p_1) &:= \pi(p_0) r(p_1, p_0) / r(p_0, p_1) \\ \pi(p_2) &:= \pi(p_1) r(p_2, p_1) / r(p_1, p_2) \\ &\dots \\ \pi(p_n) &:= \pi(p_{n-1}) r(p_n, p_{n-1}) / r(p_{n-1}, p_n).\end{aligned}$$

Thus, $\pi(y)$ (the $\pi(p_n)$) is constructed out of $\pi(x)$ (the $\pi(p_0)$). Let $\rho(x, y) := \ln r(x, y) - \ln r(y, x)$, it becomes

$$\ln \pi(y) = \ln \pi(x) + \sum_{i=0}^{n-1} \rho(p_{i+1}, p_i),$$

or in continuous format,

$$\ln \pi(y) = \ln \pi(x) + \int_P ds \rho(s), \quad (12)$$

where $\rho(s)$ is short for $\rho(p_{s+1}, p_s)$ along the path P . In this way, given $x_0 \in \mathcal{X}$, we define any $x \in \mathcal{X}$ that is connected to x_0 by $\ln \pi(x) := \ln \pi(x_0) + \int_P ds \rho(s)$. And $\pi(x_0)$ is determined by the normalization of π .

But, there can be multiple paths from x to y which are connected in \mathcal{X} . For example, consider two paths P and P' , then we have $\int_P ds \rho(s) = \int_{P'} ds \rho(s)$. Generally, if C is a **circle** which is a path starting at an element $x \in \mathcal{X}$ and finally end at x (but not simply standing at x), then

$$\oint_C ds \rho(s) = 0. \quad (13)$$

It means every path along two connected elements in \mathcal{X} is equivalent. If the condition 13 holds, we can simplify the notation in equation 12 by

$$\ln \pi(y) = \ln \pi(x) + \int_x^y ds \rho(s),$$

where \int_x^y indicates any path from x to y (if x and y are connected).

Condition 13 implies that the previous construction does define a π that holds the detailed balance condition. Given $x, y \in \mathcal{X}$, we have $\ln \pi(x) = \ln \pi(x_0) + \int_{x_0}^x ds \rho(s)$ and $\ln \pi(y) = \ln \pi(x_0) + \int_{x_0}^y ds \rho(s)$. If x and y are connected, then, by condition 13, $\rho(y, x) = \int_x^{x_0} ds \rho(s) + \int_{x_0}^y ds \rho(s)$ (the $\rho(y, x)$ indicates the path (x, y) , “jumping” directly from x to y), thus $\ln \pi(y) = \ln \pi(x) + \rho(y, x)$, which is just the detailed balance condition 6. And if x and y are not connected, then both $r(x, y)$ and $r(y, x)$ shall vanish (recall the requirements of transition rate in section 2.2: if $r(x, y) = 0$, then $r(y, x) = 0$), and detailed balance condition holds naturally.

So, condition 13 is *essential and sufficient for the existence of π that holds the detailed balance condition 6*. If \mathcal{X} is a simply connected smooth manifold, then using Stokes’s theorem, we have $\nabla \times \rho = 0$ on \mathcal{X} . But, generally \mathcal{X} is neither simply connected nor smooth, but involving independent subsystems and discrete. In these cases, condition 13 becomes very complicated.

In many applications, we consider the inverse question: given a density function, if there exists a transition rate such that detailed balance condition holds. This inverse problem is much easier, and a proper transition rate can be constructed out of the density function (such as in Metropolis-Hastings algorithm).

3. KRAMERS-MOYAL EXPANSION AND LANGEVIN DYNAMICS

We follow the discussion in section 2, but focusing on the specific situation where there is extra smooth structure on X . This smoothness reflects on the connectivity of the alphabet \mathcal{X} , and on the smooth “spatial” dependence of the density function and transition rate. This indicates that the conclusions in section 2 hold in this section, but the inverse is not guaranteed.

3.1. Spatial Expansion of Master Equation Gives Kramers-Moyal Expansion

Let the alphabet $\mathcal{X} = \mathbb{R}^n$ for some integer $n \geq 1$, which has sufficient connectivity. In addition, suppose that the density function $p(x, t)$ of a time-dependent distribution $P(t)$ and the transition rate $r(x, y)$ are smooth on x and y . In this section, we investigate the direct results of spatial smoothness.

Now, the master equation 3 becomes

$$\frac{\partial p}{\partial t}(x, t) = \int_{\mathbb{R}^n} dy r(x, y) p(y, t).$$

The spatial smoothness indicates that we can Taylor expand the right hand side to arbitrary order. The quantity that is used to perform the Taylor expansion neither x nor y since they are equally weighted, but their difference, $\epsilon := x - y$. If we replace the y in the right hand side with $x - \epsilon$, that is, $\int_{\mathbb{R}^n} dy r(x, y) p(y, t) = \int_{\mathbb{R}^n} d\epsilon r(x, x - \epsilon) p(x - \epsilon, t)$, and directly Taylor expand by ϵ , then we will get the leading term $\int_{\mathbb{R}^n} d\epsilon r(x, x) p(x, t)$, the result of which is unknown. What we have known is $\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) p(x, t)$ which is zero because of the “normalization” of transition density. So, we expect to Taylor expand by ϵ that which results in a leading term $\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) p(x, t)$. To do this, we need a little magic.

First of all, we have the identity

$$\int_{\mathbb{R}^n} d\epsilon r(x, x - \epsilon) p(x - \epsilon, t) = \int_{\mathbb{R}^n} d\epsilon r((x - \epsilon) + \epsilon, x - \epsilon) p(x - \epsilon, t).$$

Next, we perform the magic. We first define $\omega(x, \epsilon) := r(x + \epsilon, x)$, which the factor we want to obtain in the leading term. Then, the integral turns to be $\int_{\mathbb{R}^n} d\epsilon \omega(x - \epsilon, \epsilon) p(x - \epsilon, t)$. The key is Taylor expanding by the ϵ in the first argument of $\omega(x - \epsilon, \epsilon)$ in addition to that in $p(x - \epsilon, t)$. So, it becomes

$$\int_{\mathbb{R}^n} d\epsilon \omega(x, \epsilon) p(x, t) + \int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \sum_{k=1}^{+\infty} \frac{(-1)^k}{k!} \left(\frac{\partial}{\partial x^{\alpha_1}} \dots \frac{\partial}{\partial x^{\alpha_k}} \right) [\omega(x, \epsilon) p(x, t)].$$

The leading term (the first one) vanishes, as expected. With some re-arrangement to the second term, and plugging it back to the right hand side of master equation, we find

$$\frac{\partial p}{\partial t}(x, t) = \sum_{k=1}^{+\infty} \frac{(-1)^k}{k!} \left(\frac{\partial}{\partial x^{\alpha_1}} \dots \frac{\partial}{\partial x^{\alpha_k}} \right) \left[p(x, t) \int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \omega(x, \epsilon) \right].$$

The integral $\int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \omega(x, \epsilon)$ in the $[\dots]$ factor has an intuitive meaning. Remind of $\omega(x, \epsilon) = r(x + \epsilon, x)$ and $q_{\Delta t}(x + \epsilon | x) = \delta(\epsilon) + r(x + \epsilon, x) \Delta t + o(\Delta t)$, we have

$$\int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) q_{\Delta t}(x + \epsilon | x) = \Delta t \int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \omega(x, \epsilon) + o(\Delta t).$$

So, $\Delta t \int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \omega(x, \epsilon)$ is recognized as an approximation of the k -order correlation of ϵ sampled from transition density $q_{\Delta t}(x + \epsilon | x)$ (regarding $q_{\Delta t}(x + \epsilon | x)$ as an x -dependent distribution $Q_{\Delta t}(x)$ that samples ϵ). We denote it by K for the leading consonant of “correlation”

$$K^{\alpha_1 \dots \alpha_k}(x) := \int_{\mathbb{R}^n} d\epsilon (\epsilon^{\alpha_1} \dots \epsilon^{\alpha_k}) \omega(x, \epsilon).$$

Finally, we arrive at

$$\frac{\partial p}{\partial t}(x, t) = \sum_{k=1}^{+\infty} \frac{(-1)^k}{k!} \left(\frac{\partial}{\partial x^{\alpha_1}} \dots \frac{\partial}{\partial x^{\alpha_k}} \right) [K^{\alpha_1 \dots \alpha_k}(x) p(x, t)]. \quad (14)$$

This Taylor expansion of master equation is called the **Kramers–Moyal expansion**.

3.2. Transition Density of Langevin Dynamics Is Approximately Gaussian

Spatial connectivity enables us to investigate the most general distribution of continuous random variable, the normal distribution. Given $\mu: \mathbb{R}^n \rightarrow \mathbb{R}^n$ and $\Sigma: \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$, which is positive definite and symmetric, let $q_{\Delta t}(x'|x)$ the normal distribution of $x' - x$ with mean value $\mu(x) \Delta t$ and variance $2\Sigma(x)\Delta t$. That is,

$$q_{\Delta t}(x + \epsilon|x) = \frac{1}{\sqrt{(4\pi\Delta t)^n \det \Sigma(x)}} \exp\left(-\frac{1}{4\Delta t} [\Sigma^{-1}(x)]_{\alpha\beta} (\epsilon^\alpha - \mu^\alpha(x) \Delta t) (\epsilon^\beta - \mu^\beta(x) \Delta t)\right).$$

When Δt is sufficiently small, $q_{\Delta t}$ can be approximately regarded as a transition density (section 2.3). The corresponding Markov process is called **Langevin dynamics**.

In many textures, Langevin dynamics is written by a stochastic differential equation (again, we use capital letters for random variables)

$$dX^\alpha = \mu^\alpha(x)dt + dW^\alpha(x),$$

where $dW^\alpha(x)$, called **Wiener process**, is a random variable obeying the normal distribution with zero mean and variance $2\Sigma(x)dt$. This stochastic differential equation is an formal equivalent of $q_{\Delta t}(x + \epsilon|x)$ when $\Delta t \rightarrow dt$ and $\epsilon \rightarrow dx$.

3.3. Transition Rate of Langevin Dynamics Is a Generalized Function

In this section, we calculate the the transition rate of Langevin dynamics from transition density. The Δt appears in many places in transition density, and directly Taylor expanding $q_{\Delta t}$ by Δt is very hard. Instead, we employ an arbitrary test function $f \in S(\mathbb{R}^n, \mathbb{R})$,⁹ and Taylor expand f by its variable

$$\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) f(\epsilon) = \int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) \left[f(0) + \epsilon^\alpha \partial_\alpha f(0) + \frac{1}{2} \epsilon^\alpha \epsilon^\beta \partial_\alpha \partial_\beta f(0) + \dots \right]$$

These Gaussian integrals result in

$$\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) \epsilon^\alpha = \mu^\alpha(x) \Delta t$$

and (recall the relation between covariance and mean, $\text{Cov}(X, Y) = \mathbb{E}[XY] - \mathbb{E}[X] \mathbb{E}[Y]$)

$$\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) \epsilon^\alpha \epsilon^\beta = \Sigma^{\alpha\beta}(x) \Delta t + \mu^\alpha(x) \mu^\beta(x) \Delta t^2 = \Sigma^{\alpha\beta}(x) \Delta t + o(\Delta t).$$

Altogether,

$$\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) f(\epsilon) = f(0) + \Delta t [\mu^\alpha(x) \partial_\alpha f(0) + \Sigma^{\alpha\beta}(x) \partial_\alpha \partial_\beta f(0)] + o(\Delta t),$$

as $\Delta t \rightarrow 0$ (for example, $\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) [\epsilon^\alpha \epsilon^\beta \epsilon^\gamma \epsilon^\delta \partial_\alpha \partial_\beta \partial_\gamma \partial_\delta f(0)] = \mathcal{O}(\Delta t^2) = o(\Delta t)$). On the other hand, if we Taylor expand $q_{\Delta t}$ by Δt as $q_{\Delta t}(x + \epsilon|x) = \delta(\epsilon) + r(x + \epsilon, x) \Delta t + o(\Delta t)$, where r is the transition rate, then we will get

$$\int_{\mathbb{R}^n} d\epsilon q_{\Delta t}(x + \epsilon|x) f(\epsilon) = f(0) + \Delta t \int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) f(\epsilon) + o(\Delta t).$$

From the terms proportional to Δt , we recognize

$$\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) f(\epsilon) = \mu^\alpha(x) \partial_\alpha f(0) + \Sigma^{\alpha\beta}(x) \partial_\alpha \partial_\beta f(0).$$

⁹ The S represents Schwarts space, which is a functional space in which any function $f: X \rightarrow Y$ is smooth and rapidly falls to zero in the region far from origin. For example, Gaussian function (the density function of normal distribution) is in $S(\mathbb{R}, \mathbb{R})$.

Noticing the integration by parts¹⁰

$$-\int_{\mathbb{R}^n} d\epsilon \mu^\alpha(x) \partial_\alpha \delta(\epsilon) f(\epsilon) = \int_{\mathbb{R}^n} d\epsilon \mu^\alpha(x) \delta(\epsilon) \partial_\alpha f(\epsilon) = \mu^\alpha(x) \partial_\alpha f(0),$$

and

$$\int_{\mathbb{R}^n} d\epsilon \Sigma^{\alpha\beta}(x) \partial_\alpha \partial_\beta \delta(\epsilon) f(\epsilon) = \int_{\mathbb{R}^n} d\epsilon \Sigma^{\alpha\beta}(x) \delta(\epsilon) \partial_\alpha \partial_\beta f(\epsilon) = \Sigma^{\alpha\beta}(x) \partial_\alpha \partial_\beta f(0),$$

we get

$$r(x + \epsilon, x) = -\mu^\alpha(x) \partial_\alpha \delta(\epsilon) + \Sigma^{\alpha\beta}(x) \partial_\alpha \partial_\beta \delta(\epsilon). \quad (15)$$

Because of the Dirac's δ -functions, this transition rate is a generalized function. That is, only when applied to a test function can they be evaluated.

For example, to evaluate $\partial_\alpha \delta(-x)$, we have to employ an arbitrary test function $f \in S(\mathbb{R}^n, \mathbb{R}^n)$, and calculate $\int_{\mathbb{R}^n} dx \partial_\alpha \delta(-x) f^\alpha(x)$. First, notice that $\partial_\alpha \delta(-x)$ is in fact $(\partial_\alpha \delta)(-x)$ and that $(\partial \delta / \partial x^\alpha)(-x) = -(\partial / \partial x^\alpha) \delta(-x)$, thus

$$\int_{\mathbb{R}^n} dx \partial_\alpha \delta(-x) f^\alpha(x) = \int_{\mathbb{R}^n} dx (\partial_\alpha \delta)(-x) f^\alpha(x) = - \int_{\mathbb{R}^n} dx \partial_\alpha [\delta(-x)] f^\alpha(x).$$

Then, integration by parts gives $-\int_{\mathbb{R}^n} dx \partial_\alpha [\delta(-x)] f^\alpha(x) = \int_{\mathbb{R}^n} dx \delta(-x) \partial_\alpha f^\alpha(x)$. After inserting the relation $\delta(x) = \delta(-x)$, we arrive at $\int_{\mathbb{R}^n} dx \partial_\alpha \delta(-x) f^\alpha(x) = \partial_\alpha f^\alpha(0)$. On the other hand, we have, by integration by parts, $-\int_{\mathbb{R}^n} dx \partial_\alpha \delta(x) f^\alpha(x) = \int_{\mathbb{R}^n} dx \delta(x) \partial_\alpha f^\alpha(x) = \partial_\alpha f^\alpha(0)$. Altogether, we find $\int_{\mathbb{R}^n} dx \partial_\alpha \delta(-x) f^\alpha(x) = -\int_{\mathbb{R}^n} dx \partial_\alpha \delta(x) f^\alpha(x)$, for any $f \in S(\mathbb{R}^n, \mathbb{R}^n)$. Thus, $\partial_\alpha \delta(-x)$ is evaluated to be $-\partial_\alpha \delta(x)$. That is, $\partial_\alpha \delta$ is *odd*. Following the same process, we can show that $\partial_\alpha \partial_\beta \delta$ is *even*.¹¹ These conclusions are to be used in section 3.6.

¹⁰. High-dimensional integration by parts employs Stokes theorem. Consider the integral $\int_{\mathbb{R}^n} dx \partial_\alpha \varphi(x) v^\alpha(x)$ with smooth scalar function $\varphi: \mathbb{R}^n \rightarrow \mathbb{R}$ and vector field $v: \mathbb{R}^n \rightarrow \mathbb{R}^n$. We have identity

$$\int_{\mathbb{R}^n} dx \partial_\alpha \varphi(x) v^\alpha(x) = \int_{\mathbb{R}^n} dx \partial_\alpha [\varphi(x) v^\alpha(x)] - \int_{\mathbb{R}^n} dx \varphi(x) \partial_\alpha v^\alpha(x).$$

The first integrand in the right hand side is a divergence. Using Stokes theorem, it becomes

$$\int_{\partial \mathbb{R}^n} dS_\alpha [\varphi(x) v^\alpha(x)],$$

where $\partial \mathbb{R}^n$ is the "boundary" of \mathbb{R}^n . If φ or v is in Schwarts space, then this term vanishes, and the integral results in

$$\int_{\mathbb{R}^n} dx \partial_\alpha \varphi(x) v^\alpha(x) = - \int_{\mathbb{R}^n} dx \varphi(x) \partial_\alpha v^\alpha(x).$$

¹¹. We are to calculate $\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(-x) f^{\alpha\beta}(x)$, where $f \in S(\mathbb{R}^n, \mathbb{R}^{n \times n})$. Again, noticing that $(\partial_\alpha \partial_\beta \delta)(-x) = \partial_\alpha \partial_\beta [\delta(-x)]$, we have

$$\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(-x) f^{\alpha\beta}(x) = \int_{\mathbb{R}^n} dx (\partial_\alpha \partial_\beta \delta)(-x) f^{\alpha\beta}(x) = \int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta [\delta(-x)] f^{\alpha\beta}(x).$$

Then integration by parts gives

$$\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta [\delta(-x)] f^{\alpha\beta}(x) = \int_{\mathbb{R}^n} dx \delta(-x) \partial_\alpha \partial_\beta f^{\alpha\beta}(x) = \partial_\alpha \partial_\beta f^{\alpha\beta}(0).$$

That is, $\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(-x) f^{\alpha\beta}(x) = \partial_\alpha \partial_\beta f^{\alpha\beta}(0)$. On the other hand, we have

$$\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(x) f^{\alpha\beta}(x) = \int_{\mathbb{R}^n} dx \delta(x) \partial_\alpha \partial_\beta f^{\alpha\beta}(x) = \partial_\alpha \partial_\beta f^{\alpha\beta}(0).$$

So,

$$\int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(-x) f^{\alpha\beta}(x) = \int_{\mathbb{R}^n} dx \partial_\alpha \partial_\beta \delta(x) f^{\alpha\beta}(x)$$

holds for any $f \in S(\mathbb{R}^n, \mathbb{R}^{n \times n})$, thus $\partial_\alpha \partial_\beta \delta(-x) = \partial_\alpha \partial_\beta \delta(x)$.

3.4. Master Equation of Langevin Dynamics Is Fokker-Planck Equation

After discussing transition rate, we turn to the master equation of Langevin dynamics. Since Langevin dynamics applies to continuous random variable, we can use Kramers-Moyal expansion to evaluate its master equation. Directly, we have $K^\alpha(x) = \mu^\alpha(x)$, $K^{\alpha\beta}(x) = 2\Sigma^{\alpha\beta}(x)$, and higher orders are all vanishing (K was defined in section 3.1). For example, the integral $\int_{\mathbb{R}^n} d\epsilon (\epsilon^\alpha \epsilon^\beta \epsilon^\gamma) q_{\Delta t}(x + \epsilon|x) = o(\Delta t)$. By relation $\int_{\mathbb{R}^n} d\epsilon (\epsilon^\alpha \epsilon^\beta \epsilon^\gamma) q_{\Delta t}(x + \epsilon|x) = \Delta t K^{\alpha\beta\gamma}(x) + o(\Delta t)$ (derived in section 3.1), we find $K^{\alpha\beta\gamma}(x) = 0$. Thus, Kramers-Moyal expansion 14 reads

$$\frac{\partial p}{\partial t}(x, t) = -\partial_\alpha(\mu^\alpha(x) p(x, t)) + \partial_\alpha \partial_\beta (\Sigma^{\alpha\beta}(x) p(x, t)). \quad (16)$$

This equation is called **Fokker-Planck equation**, found by Adriaan Fokker and Max Planck in 1914 and 1917 respectively, or **Kolmogorov forward equation**, independently discovered in 1931.

3.5. Stationary Solution of Fokker-Planck Equation

Fokker-Planck equation 16 has stationary solution Π which satisfies (since there is only one variable x , we use ∂ instead of ∇)

$$-\partial_\alpha(\mu^\alpha(x) \pi(x)) + \partial_\alpha \partial_\beta (\Sigma^{\alpha\beta}(x) \pi(x)) = 0,$$

which means

$$\mu^\alpha(x) \pi(x) = \partial_\beta (\Sigma^{\alpha\beta}(x) \pi(x)) + \nu^\alpha(x), \quad (17)$$

where $\nu: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is an arbitrary vector field such that $\partial_\alpha \nu^\alpha(x) = 0$.

The vector field ν has an intuitive explanation. Regarding ν as a flux on \mathbb{R}^n , we find that there is not net flux flowing out of anywhere in \mathbb{R}^n . Otherwise, suppose there is $x \in \mathbb{R}^n$ and a closed surface S around x such that the net flux $\int dS \cdot \nu(x)$ does not vanish. Then, by Stokes theorem, the surface integral $\int dS \cdot \nu(x) = \int dx \nabla \cdot \nu(x) = 0$, thus conflicts. Such a vector field ν is called **free of source** or **source-free**.

3.6. Detailed Balance Condition for Langevin Dynamics Lacks Source-Free Degree of Freedom

After discussing stationary distribution of Fokker-Planck equation (as a master equation), we continue investigate when will Langevin dynamics relax an initial distribution to the stationary. By theorem 1, this is equivalent to ask: when will the transition rate of Langevin dynamics satisfy detailed balance condition? Detailed balance condition reads $r(x + \epsilon, x) \pi(x) = r(x, x + \epsilon) \pi(x + \epsilon)$. Directly inserting equation 15, we get, for the left hand side,

$$r(x + \epsilon, x) \pi(x) = -\mu^\alpha(x) \pi(x) \partial_\alpha \delta(\epsilon) + \Sigma^{\alpha\beta}(x) \pi(x) \partial_\alpha \partial_\beta \delta(\epsilon),$$

and, for the right hand side,

$$\begin{aligned} & r(x, x + \epsilon) \pi(x + \epsilon) \\ &= r((x + \epsilon) - \epsilon, x + \epsilon) \pi(x + \epsilon) \\ &= -\mu^\alpha(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \delta(-\epsilon) + \Sigma^{\alpha\beta}(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \partial_\beta \delta(-\epsilon) \\ &= \mu^\alpha(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \delta(\epsilon) + \Sigma^{\alpha\beta}(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \partial_\beta \delta(\epsilon), \end{aligned}$$

where in the last line, we use $\partial_\alpha \delta(-x) = -\partial_\alpha \delta(x)$ and $\partial_\alpha \partial_\beta \delta(-x) = \partial_\alpha \partial_\beta \delta(x)$.

As generalized functions, we are to examine these two expressions by using an arbitrary test function f . Thus, for the left hand side,

$$\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) \pi(x) f(\epsilon) = - \int_{\mathbb{R}^n} d\epsilon \mu^\alpha(x) \pi(x) \partial_\alpha \delta(\epsilon) f(\epsilon) + \int_{\mathbb{R}^n} d\epsilon \Sigma^{\alpha\beta}(x) \pi(x) \partial_\alpha \partial_\beta \delta(\epsilon) f(\epsilon).$$

Integration by parts gives (note that the ∂ is applied on ϵ)

$$\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) \pi(x) f(\epsilon) = \mu^\alpha(x) \pi(x) \partial_\alpha f(0) + \Sigma^{\alpha\beta}(x) \pi(x) \partial_\alpha \partial_\beta f(0).$$

The right hand side is a little complicated,

$$\int_{\mathbb{R}^n} d\epsilon r(x, x + \epsilon) \pi(x + \epsilon) f(\epsilon) = \int_{\mathbb{R}^n} d\epsilon \mu^\alpha(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \delta(\epsilon) f(\epsilon) + \int_{\mathbb{R}^n} d\epsilon \Sigma^{\alpha\beta}(x + \epsilon) \pi(x + \epsilon) \partial_\alpha \partial_\beta \delta(\epsilon) f(\epsilon).$$

Again, integration by parts results in (again, the ∂ is applied on ϵ)

$$\begin{aligned} & \int_{\mathbb{R}^n} d\epsilon r(x, x + \epsilon) \pi(x + \epsilon) f(\epsilon) \\ &= - \int_{\mathbb{R}^n} d\epsilon \delta(\epsilon) \frac{\partial}{\partial \epsilon^\alpha} [\mu^\alpha(x + \epsilon) \pi(x + \epsilon) f(\epsilon)] \\ &+ \int_{\mathbb{R}^n} d\epsilon \delta(\epsilon) \frac{\partial^2}{\partial \epsilon^\alpha \partial \epsilon^\beta} [\Sigma^{\alpha\beta}(x + \epsilon) \pi(x + \epsilon) f(\epsilon)] \\ &= -\partial_\alpha [\mu^\alpha(x) \pi(x)] f(0) - \mu^\alpha(x) \pi(x) \partial_\alpha f(0) \\ &+ \partial_\alpha \partial_\beta [\Sigma^{\alpha\beta}(x) \pi(x)] f(0) + 2\partial_\beta [\Sigma^{\alpha\beta}(x) \pi(x)] \partial_\alpha f(0) + \Sigma^{\alpha\beta}(x) \pi(x) \partial_\alpha \partial_\beta f(0). \end{aligned}$$

By equaling $\int_{\mathbb{R}^n} d\epsilon r(x + \epsilon, x) \pi(x) f(\epsilon)$ and $\int_{\mathbb{R}^n} d\epsilon r(x, x + \epsilon) \pi(x + \epsilon) f(\epsilon)$, since f is arbitrary, we find, for the $f(0)$ terms,

$$-\partial_\alpha (\mu^\alpha(x) \pi(x)) + \partial_\alpha \partial_\beta (\Sigma^{\alpha\beta}(x) \pi(x)) = 0,$$

and for $\partial f(0)$ terms,

$$-\mu^\alpha(x) \pi(x) + \partial_\beta (\Sigma^{\alpha\beta}(x) \pi(x)) = 0.$$

The $\partial\partial f(0)$ terms vanishes automatically. Altogether, we find the detailed balance condition for Langevin dynamics to be

$$\mu^\alpha(x) \pi(x) = \partial_\beta (\Sigma^{\alpha\beta}(x) \pi(x)). \quad (18)$$

Comparing with the stationary Fokker-Planck equation 17, the source-free vector field ν is absent here. Recall in section 2.4 where detailed balance condition was first encountered, we said that detailed balance condition is stronger than just being stationary. Now, in Langevin dynamics, this becomes concrete: *detailed balance condition is stronger than stationary condition in the sense that it lacks the source-free degree of freedom that appears in the stationary condition.* The lost degree of freedom is the cost of ensuring that any initial distribution will finally relax to the stationary.

4. MAXIMUM-ENTROPY PRINCIPLE

4.1. Conventions in This Section

Follow the conventions in section 2.

4.2. Maximum-Entropy Principle Shall Minimize Relative Entropy

As discussed in section 1, Shannon entropy is not well-defined for continuous random variable, while the relative entropy is proper for both discrete and continuous random variables. Comparing with Shannon entropy, relative entropy needs an extra distribution, which describes the prior knowledge. It then characterizes the relative uncertainty (surprise) of a distribution to the distribution of prior knowledge. When the prior knowledge is unbiased and $|\mathcal{X}| := \int_{\mathcal{X}} dx 1 < +\infty$, the negative relative entropy reduces to Shannon entropy. So, maximum-entropy principle shall minimize relative entropy.

Given a distribution P_0 that describes the prior knowledge of random variable X , the basic problem is to find a distribution P of X such that the relative entropy $H(P, P_0)$ is minimized under a set of restrictions $\{\mathbb{E}_P[f_\alpha] = \bar{f}_\alpha | \alpha = 1, \dots, m, f_\alpha: \mathcal{X} \rightarrow \mathbb{R}\}$. The notation $\mathbb{E}_P[\dots] := \int_{\mathcal{X}} dx p(x) \dots$ represents expectation under P ; and the function f_α is called **observable** and the value \bar{f}_α is called an **observation**. Thus, P is the distribution that is closest to the prior knowledge with the restrictions fulfilled.

To solve this problem, we use variational principle with Lagrangian multipliers. There are two kinds of constraints. One from the restrictions $\mathbb{E}_P[f_\alpha] = \bar{f}_\alpha$ for each α ; and the other from normalization $\int_{\mathcal{X}} dx p(x) = 1$. Recall that the relative entropy $H(P, P_0) := \int_{\mathcal{X}} dx p(x) \ln(p(x)/p_0(x))$. Altogether, the loss functional becomes

$$L(p, \lambda, \mu) := \int_{\mathcal{X}} dx p(x) \ln \frac{p(x)}{p_0(x)} + \lambda^\alpha \left(\int_{\mathcal{X}} dx p(x) f_\alpha(x) - \bar{f}_\alpha \right) + \mu \left(\int_{\mathcal{X}} dx p(x) - 1 \right). \quad (19)$$

So, we have (L is a functional of p , thus use δ instead of ∂ for p),

$$\begin{aligned} \frac{\delta L}{\delta p(x)}(p, \lambda, \mu) &= \ln p(x) + 1 - \ln p_0(x) + \lambda^\alpha f_\alpha(x) + \mu; \\ \frac{\partial L}{\partial \lambda^\alpha}(p, \lambda, \mu) &= \int_{\mathcal{X}} dx p(x) f_\alpha(x) - \bar{f}_\alpha; \\ \frac{\partial L}{\partial \mu}(p, \lambda, \mu) &= \int_{\mathcal{X}} dx p(x) - 1. \end{aligned}$$

These equations shall vanish on the extremum. If $(p_\star, \lambda_\star, \mu_\star)$ is an extremum, then

$$\frac{\partial \ln Z}{\partial \lambda^\alpha}(\lambda_\star) + \bar{f}_\alpha = 0 \quad (20)$$

for each $\alpha = 1, \dots, m$, where

$$Z(\lambda) := \int_{\mathcal{X}} dx p_0(x) \exp(-\lambda^\alpha f_\alpha(x)); \quad (21)$$

and

$$p_\star(x) = p(x, \lambda_\star), \quad (22)$$

where

$$p(x, \lambda) := p_0(x) \exp(-\lambda^\alpha f_\alpha(x)) / Z(\lambda). \quad (23)$$

The μ_\star has been included in the Z .

4.3. Prior Knowledge Furnishes Free Theory or Regulator

Compared with the maximum-entropy principle derived from maximizing Shannon entropy, we get an extra factor $p_0(x)$ in $p(x, \lambda)$. This factor plays the role of prior knowledge.

In physics, this prior knowledge can be viewed as free theory, a theory without interactions. Indeed, interaction shall be given by the restrictions, the expectations of observables. It is the factor $\exp(-\lambda^\alpha f_\alpha(x))$ in $p(x, \lambda)$. The λ plays the role of couplings. This indicates that $p_0(x)$ shall be the free theory.

In machine learning, it acts as regulator, a pre-determined term employed for regulating the value of x .

5. LEAST-ACTION PRINCIPLE

In this section, we are to find a way of extracting dynamics (action or Lagrangian) from any raw data of any entity.

5.1. Conventions in This Section

Follow the conventions in section 2. In addition, we use $P(\theta)$ for a parameterized distribution, where θ is the collection of parameters. Its density function is $p(x, \theta)$, where random variable X takes the value x .

5.2. Data Fitting Is Equivalent to Least-Action Principle

Let $P(\theta)$ represent a parametrized distribution of X , and P_0 a distribution of X that represents prior knowledge as in the case of maximum-entropy principle. Let $V(x, \theta) := -\ln(p(x, \theta)/p_0(x)) - \ln Z(\theta)$ with $Z(\theta)$ to be determined. Density \hat{p} is essential for defining V , since $\ln p(x, \theta)$ is not well-defined (section 1.3). Then, we can re-formulate $p(x, \theta)$ as

$$p(x, \theta) = p_0(x) \exp(-V(x, \theta)) / Z(\theta), \quad (24)$$

and since $\int_{\mathcal{X}} dx p(x, \theta) = 1$,

$$Z(\theta) = \int_{\mathcal{X}} dx p_0(x) \exp(-V(x, \theta)). \quad (25)$$

As a generic form of a parameterized distribution, it can be used to fit raw data that obeys an empirical distribution Q , by adjusting parameter θ . To do so, we minimize the relative entropy between Q and $P(\theta)$, which is defined as $H(Q, P(\theta)) := \int_{\mathcal{X}} dx q(x) \ln(q(x)/p(x, \theta))$. Plugging equation 24 into $H(Q, P(\theta))$, we have

$$H(Q, P(\theta)) = \int_{\mathcal{X}} dx q(x) \ln q(x) - \int_{\mathcal{X}} dx q(x) \ln p_0(x) + \int_{\mathcal{X}} dx q(x) V(x, \theta) + \int_{\mathcal{X}} dx q(x) \ln Z(\theta).$$

By omitting the θ -independent terms, we get the loss function

$$L(\theta) := \mathbb{E}_Q[V(\cdot, \theta)] + \ln Z(\theta).$$

We can find the $\theta_\star := \operatorname{argmin} L$ by iteratively updating θ along the direction $-\partial L / \partial \theta$. With a series of direct calculus,¹² we find

$$-\frac{\partial L}{\partial \theta^\alpha}(\theta) = \mathbb{E}_{P(\theta)} \left[\frac{\partial V}{\partial \theta^\alpha}(\cdot, \theta) \right] - \mathbb{E}_Q \left[\frac{\partial V}{\partial \theta^\alpha}(\cdot, \theta) \right]. \quad (26)$$

At the minimum, we shall have $\partial L / \partial \theta = 0$. Then, we find that θ_\star obeys

$$\mathbb{E}_{P(\theta_\star)} \left[\frac{\partial V}{\partial \theta^\alpha}(\cdot, \theta_\star) \right] = \mathbb{E}_Q \left[\frac{\partial V}{\partial \theta^\alpha}(\cdot, \theta_\star) \right]. \quad (27)$$

It can be read from equation 26 that minimizing L is to increase $V(\cdot, \theta)$ on the sampled points (the first term) while decrease it on data points (the second term). As figure 2 illustrates, this way of optimization will site real world data onto local minima of $V(\cdot, \theta)$, in statistical sense. In this way, the $V(\cdot, \theta)$ is recognized as a parameterized action (in fact, it is the interactive part of action, and the free part locates in the prior density p_0). It describes the interaction between the different components of an entity. This entity may be of physics, like a collection of particles. But it can also be words, genes, flock of birds, and so on. For example, we can find out how words “interact” with each other.

¹². Directly, we have

$$\frac{\partial L}{\partial \theta^\alpha}(\theta) = \mathbb{E}_Q \left[\frac{\partial V}{\partial \theta^\alpha}(\cdot, \theta) \right] + Z^{-1}(\theta) \frac{\partial Z}{\partial \theta^\alpha}(\theta).$$

Since $Z(\theta) := \int dx p_0(x) \exp(-V(x, \theta))$, we find

$$\frac{\partial Z}{\partial \theta^\alpha}(\theta) = - \int dx p_0(x) \exp(-V(x, \theta)) \frac{\partial V}{\partial \theta^\alpha}(x, \theta),$$

thus

$$Z^{-1}(\theta) \frac{\partial Z}{\partial \theta^\alpha}(\theta) = - \int dx [p_0(x) \exp(-V(x, \theta))] Z^{-1}(\theta) \frac{\partial V}{\partial \theta^\alpha}(x, \theta) = - \int dx p(x, \theta) \frac{\partial V}{\partial \theta^\alpha}(x, \theta),$$

where in the last equality, we used the definition of $p(x, \theta)$ (the blue parts). This final expression is just the $-\mathbb{E}_{P(\theta)}[(\partial V / \partial \theta^\alpha)(\cdot, \theta)]$.

Figure 2. This figure illustrate how $\min_{\theta} L(\theta)$ will site a real world datum onto a local minimum of $V(\cdot, \theta)$. The green curve represents the current not-yet-optimized $V(\cdot, \theta)$. The x_1 (red point) is a real world datum while x_2 (blue point), which is currently a local minimum of $V(\cdot, \theta)$, is not. Minimizing L by tuning θ pushes the $\mathbb{E}_Q[V(\cdot, \theta)]$ down to lower value, corresponding to the red downward double-arrow on x_1 . Also, since x_2 is a local minimum, the data points sampled from $p(x, \theta) \propto \exp(-V(x, \theta))$ will accumulate around x_2 . So, minimizing L also pulls the $\mathbb{E}_{P(\theta)}[V(\cdot, \theta)]$ up to greater value, corresponding to the blue upward double-arrow on x_2 . Altogether, it makes x_1 a local minimum of $V(\cdot, \theta)$, and $V(\cdot, \theta)$ is optimized to be the dashed green curve.

5.3. Example: Extract Dynamics from Raw Data

We are to apply the previous discussion to extract dynamics from the raw data of an evolutionary system. Precisely, we are to fit the interactive part of action (the V in section 5.2) from the raw data of a system that evolves with time.

The raw data is obtained in the following way. Generally, an evolutionary system is described by its dynamics in configuration space. Let \mathcal{C} a configuration space (such as \mathbb{R}^3 for a particle, $\mathbb{R}^{3 \times n}$ for n particles, or $\{A, C, G, T\}^{|\text{DNA}|}$ for gene) in which the system evolves. Without losing generality, we standardize the time period of evolution to $[0, 1]$. Thus, the dynamics is characterized by a path in configuration space, $x(s) \in \mathcal{C}$ with $s \in [0, 1]$. To obtain the raw data of the system, we first uniformly separate the standardized time period $[0, 1]$ into T frames. At each frame, we use tools to measure the configuration of the system. Of course, measurement error cannot be avoided. What we get is a movie of the system, like $(x(1), \dots, x(T))$ with each $x(t) \in \mathcal{C}$. We repeat this process many times, with different initial conditions. In this way, we obtain the raw data of the evolutionary system, as a set $\{(x_k(1), \dots, x_k(T)) | k = 1, \dots, D\}$ where D is the repetitions.

The prior distribution P_0 is given before data-fitting. For example, for a physical system, P_0 represents the free theory, which does not involve interactive parameter. In this case, we have

$$p_0(x) \propto \exp \left\{ -\frac{T}{2} \sum_{t=1}^{T-1} [x(t+1) - x(t)]^2 \right\},$$

corresponding to the kinetic term $(1/2) \int_0^1 ds \dot{x}^2(s)$.

Corresponding to this free term, the interactive term V described in section 5.2 is given by some ansatz. For example, we may suppose V to be local. That is, there is a function $\mathcal{L}(x, t, \theta)$ such that $V(x, \theta) = (1/T) \sum_{t=1}^T \mathcal{L}(x(t), t, \theta)$. Or, we may suppose that there exist some symmetries about the system, such as autonomous and parity symmetry, which indicates $\mathcal{L}(x, t, \theta) = \sum_{n=1}^{+\infty} \theta_n x^{2n}$ when

x is 1-dimensional. All we need to do is constructing a most generic form of \mathcal{L} that satisfies all the ansatz. Neural network and symbolic regression may help you write down this most generic form. Then, we find the best fit θ_* by iteratively applying equation 26. The $V(x, \theta_*)$, together with the free term provided by P_0 , describes the dynamics of the evolutionary system.

As an example, consider an one-dimensional harmonic oscillator. The configuration space is \mathbb{R} . Given the parameter $\omega \in \mathbb{R}$, we can obtain the raw data by numerically simulating the equation of motion (discrete version)

$$x(t+1) - 2x(t) + x(t-1) + \left(\frac{\omega}{T}\right)^2 x(t) = 0,$$

for $t=2, \dots, T-1$. The $x(0)$ and $x(1)$ are randomly generated in each simulation as initial conditions. In the end, remember to add noise to the simulated data. Once obtained the raw data, we can use a parameterized function to fit the interactive term. For example, a function with parameters $(\theta_1, \dots, \theta_n) \in \mathbb{R}^n$, $\mathcal{L}(x, t, \theta) := \theta_1 x^2 + \theta_2 x^4 + \dots + \theta_n x^{2n}$.¹³

5.4. Maximum-Entropy and Least-Action Are Saddle Point of a Functional

In fact, equations 24, 25, and 27 can be regarded as an extremum of the functional (recall that P_0 is the distribution of prior knowledge and Q of dataset)

$$L_{\text{tot}}(p, \theta, \mu) := H[P, P_0] + (\mathbb{E}_P[V(\cdot, \theta)] - \mathbb{E}_Q[V(\cdot, \theta)]) + \mu(\mathbb{E}_P[1] - 1),$$

or explicitly

$$L_{\text{tot}}(p, \theta, \mu) = \int_{\mathcal{X}} dx p(x) \ln \frac{p(x)}{p_0(x)} + \left(\int_{\mathcal{X}} dx p(x) V(x, \theta) - \int_{\mathcal{X}} dx q(x) V(x, \theta) \right) + \mu \left(\int_{\mathcal{X}} dx p(x) - 1 \right). \quad (28)$$

Indeed, variance on p gives equation 24.¹⁴ Together with the partial derivative on μ , we get equation 25. Finally, partial derivative on θ directly gives equation 27. In addition, decreasing the $L(\theta)$ by iteration 26 is increasing the second term in equation 28. So, the extremum is in fact a saddle point, as

$$(p_*, \theta_*, \mu_*) = \min_{p, \mu} \max_{\theta} L_{\text{tot}}(p, \theta, \mu). \quad (29)$$

By tuning p , the $\min_{p, \mu}$ minimizes the relative entropy between P and Q and the expectation $\mathbb{E}_P[V(\cdot, \theta)]$, which in turn relates the density function p with the interactive action $V(\cdot, \theta)$. And by tuning θ , the \max_{θ} sites real data onto the local minima of interactive action. So, we find that maximum-entropy principle and least-action principle are saddle point of a functional L_{tot} (the subscript is short for totality).

5.5. TODO: Structures in Nature Arise from Maximum-Entropy

There are many structures in nature. The structure of vascular system is a simple instance. A more complicated structure appears in the bases along chromosome. Why does these structures arise in nature?

The vascular system is fine-tuned so as to minimize the frictional loss. The chromosome that determines the phenotype of an organism is also fine-tuned such that the probability of survival is maximal. These examples indicate that structure appears in optimizing an objective.

So, let random variable X characterize the configuration, such as the sequence of bases along chromosome. There is an action that reflects the interaction of bases and the environment. The one that survives has the most “coherent” chromosome that minimizes the action. The “survival” distribution is given by the action. This distribution has many local maxima. The maximal local maxima represents the creature that has the highest adaptation, maybe human.

¹³. An experiment on general oscillators can be found in the `oscillators/Oscillator.ipynb`.

¹⁴. Explicitly, we have

$$\frac{\delta}{\delta p(x)} L_{\text{tot}}(p, \theta, \mu) = \ln p(x) + 1 - \ln p_0(x) + V(x, \theta) + \mu = 0,$$

which has solution

$$p(x) \propto p_0(x) \exp(-V(x, \theta)).$$

The action would be very complex. But, inversely, given the real world data of chromosome, the action can be revealed by parameterized function and least-action principle. To do so, we first travel to a closed island, such as Galápagos Islands, which forms a closed system. Then, we collect the chromosomes of all creatures living on the island. Since different creatures have different lengths of chromosome, we have to unify the coding of chromosomes. This furnishes the alphabet \mathcal{X} , and the collection of chromosomes characterizes the distribution of real world data, Q . Let $S(x, \theta)$ a parameterized function, with parameters θ . The least-action principle gives the best fit θ_* by minimizing the L_{LA} . During the minimization, we have to sample from $P(\theta)$, where the density function $p(x, \theta) \propto \exp(-S(x, \theta))$. The strategy is using a transition rate that satisfies the detailed balance condition. This transition rate mimics the evolution. **The disconnectivity of transition rate may reflect gene isolation.**

5.6. TODO: Is There an Action for a Dynamical System?

Configuration can be represented by a high-dimensional vector. As discussed in section 5.3, the configuration of physical system should be a function $x(t): [0, 1] \rightarrow \mathbb{R}^m$, but discretized to a vector $(x(1), \dots, x(T)) \in \mathbb{R}^{m \times T}$ where T represents the number of frames. Thus, an action, including the free part (given by prior distribution P_0) and interactive part (the parametrized function V), can be represented as $S(x): \mathbb{R}^n \rightarrow \mathbb{R}$, where $n := m \times T$. This discrete perspective greatly simplifies the situation. For example, the variation of action is simply $-T \nabla S(x)$.

In the example of harmonic oscillator (equation 30), we have

$$S_{HO}(x) = \frac{T}{2} \sum_{t=1}^{T-1} [x(t+1) - x(t)]^2 - \frac{\omega^2}{2T} \sum_{t=1}^T x^2(t), \quad (30)$$

where we have included both the free term and interactive term in the action S_{HO} . We have¹⁵

$$-T \frac{\partial S_{HO}}{\partial x(t)} = T^2 [x(t+1) - 2x(t) + x(t-1)] + \omega^2 x(t)$$

for each $t = 2, \dots, T-1$. Recalling that $\ddot{x}(t)$ is discretized to $T^2 [x(t+1) - 2x(t) + x(t-1)]$, we find $-T \partial S_{HO} / \partial x(t)$ tends to $\ddot{x}(t) + \omega^2 x(t)$ as $T \rightarrow +\infty$. For the boundaries $t=1$ and $t=T$, we have $-T \partial S_{HO} / \partial x(1) = -T^2 [x(2) - x(1)] - \omega^2 x(1)$, and $-T \partial S_{HO} / \partial x(T) = T^2 [x(T) - x(T-1)] - \omega^2 x(T)$. Both are meaningless in continuous perspective. Thus, there are $T-2$ equations for one-dimensional harmonic oscillator obtained by variation.

On the other hand, equation of motion can be represented by $f(x) = 0$ where $f: \mathbb{R}^n \rightarrow \mathbb{R}^{n-m}$ where m represents the order of the equation of motion. In the case of one-dimensional harmonic oscillator, the equation of motion is second order. In the discrete perspective, there are $T-2$ constraints, implying $m=2$. The two extra degree of freedom are assigned to the initial position and velocity of oscillator.

If we want to represent the equation of motion by the variation of action (in the continuous perspective it is $f(t, x(t), \dot{x}(t), \dots) = \delta S / \delta x(t)$), we can write $f_\alpha(x) = -\partial_\alpha S(x)$ for each $\alpha = 1, \dots, n-m$. This cannot be true for all f since $\partial_\alpha \partial_\beta S(x) \equiv \partial_\beta \partial_\alpha S(x)$ while generally we do not have $\partial_\alpha f_\beta(x) = \partial_\beta f_\alpha(x)$. From another aspect, f has $n-m$ degree of freedom, but φ has only one. So, it is hard to equal f and $\nabla \varphi$. The extra degree of freedom of f comes from ν which has $n-m-1$ degree of freedom, where the -1 is caused by the restriction $\nabla \cdot \nu = 0$.

But, if $f(x) = 0$ is an equation of motion, so will be $A_{\alpha\beta}(x) f^\beta(x) = 0$ for any smooth and invertible matrix-valued field $A: \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$. The $Af = 0$ is an equation of motion that is equivalent to $f = 0$. So, we may expect

$$A_{\alpha\beta}(x) f^\beta(x) = -\partial_\alpha S(x) \quad (31)$$

holds for a general class of equation of motion f as long as we can find the corresponding A . We wonder, **given f , if there is such an A and an S that this relation holds? And if they do exist, can we construct the A and S by an algorithm?**

¹⁵. Given $t, x(t)$ appears in two terms in $S_{HO}(x)$, the t and $t+1$ terms in the summation. They have derivatives $T[-x(t+1) + x(t)] - (\omega^2/T)x(t)$ and $T[x(t) - x(t-1)]$ respectively. Altogether, we find $-\partial S_{HO} / \partial x(t) = T[x(t+1) - 2x(t) + x(t-1)] + (\omega^2/T)x(t)$.

In the case of damped oscillator, where the equation of motion is modified by adding a friction term to that of harmonic oscillator, we have the t -component

$$f_t(x) = T^2 [x(t+1) - 2x(t) + x(t-1)] + \gamma [x(t+1) - x(t)] + T\omega^2 x(t).$$

It is found that the action

$$S_{\text{DO}}(x) = \frac{T}{2} \sum_{t=1}^{T-1} \exp\left(\frac{\gamma t}{T}\right) [x(t+1) - x(t)]^2 - \frac{\omega^2}{2T} \sum_{t=1}^T \exp\left(\frac{\gamma t}{T}\right) x^2(t)$$

has partial derivative¹⁶

$$-T \frac{\partial S_{\text{DO}}}{\partial x(t)} = \exp\left(\frac{\gamma t}{T}\right) \{T^2 [x(t+1) - 2x(t) + x(t-1)] + \gamma [x(t+1) - x(t)] + T\omega^2 x(t)\}$$

for each for $t = 2, \dots, T-1$. It is exactly the equation of motion of damped oscillator multiplied by the factor $\exp(\gamma t/T)$. In this example, the matrix-valued field A is diagonal and constant (that is, independent of x), $A^{tt'} = \delta^{tt'} \exp(\gamma t/T)$ (index is the frame number t , see section 5.3).

¹⁶. Again, given t , there are two terms in $S_{\text{DO}}(x)$ that contains $x(t)$, the t and $t-1$ terms in the summation. They have derivatives

$$\exp\left(\frac{\gamma t}{T}\right) T [-x(t+1) + x(t)] - \exp\left(\frac{\gamma t}{T}\right) \left(\frac{\omega^2}{T}\right) x(t)$$

and

$$\exp\left(\frac{\gamma(t-1)}{T}\right) T [x(t) - x(t-1)] = \exp\left(\frac{\gamma t}{T}\right) T [x(t) - x(t-1)] - \left(1 - \exp\left(-\frac{\gamma}{T}\right)\right) \exp\left(\frac{\gamma t}{T}\right) T [x(t) - x(t-1)]$$

respectively. The factor $1 - \exp(-\gamma/T) = \gamma/T + o(1/T)$. Thus, altogether, $-\partial S_{\text{DO}}/\partial x(t) = \exp(\gamma t/T) \{T [x(t+1) - 2x(t) + x(t-1)] + \gamma [x(t) - x(t-1)] + (\omega^2/T) x(t)\}$.
